Declaration

We hereby declare that the report titled **SECURE IMAGE TRANSMISSION ON RISC-V: A HARDWARE IMPLEMENTATION OF HYBRID POST QUANTUM PROTOCOL** submitted by us to the School of Electronics Engineering, Vellore Institute of Technology, Chennai, in partial fulfilment of the requirements for the award of **Bachelor of Technology** in **Electronics and Communication Engineering,** is a bonafide record of the work carried out by us under the supervision of **Dr SANKAR GANESH**.

We further declare that the work reported in this report has not been submitted and will not be submitted, either in part or in full, for the award of any other degree or diploma of this institute or of any other institute or University.

Abstract

Quantum computers aren't just a theoretical concern anymore, they're becoming real, and that's a problem for our current security systems. The RSA and ECC algorithms that we rely on today; Shor's algorithm can break them efficiently once we have sufficiently powerful quantum machines. This realization is what led toward exploring post-quantum cryptography.

This project deals with implementing CRYSTALS-Kyber, which NIST finally standardized in 2024 after years of evaluation. We built a working system that uses Kyber for key exchange combined with AES-256 for actually encrypting image files. The setup has two parts: a host application running on a regular computer (Windows with MSYS2), and a receiver module designed for RISC-V processors that can run on actual FPGA hardware or just simulation.

The implementation handles the complete workflow, which consists of generating keys, encapsulating them, encrypting images, and decrypting them back. We tested it with different image sizes and formats to see if everything works correctly. The results show that while Kyber adds some overhead compared to traditional methods, it's manageable and gives us security that should hold up even against quantum attacks.

For embedded systems like IoT devices or secure communication modules, this kind of implementation matters because we can't just upgrade hardware easily once deployed. Getting this working on RISC-V specifically is useful since it's an open architecture gaining traction in embedded spaces.

Acknowledgements

We wish to express our sincere thanks and deep sense of gratitude to our project guide, **Dr. Sankar Ganesh**, Professor, School of Electronics Engineering (SENSE), for his consistent encouragement and valuable guidance offered to us in a pleasant manner throughout the course of the project work.

We sincerely express our gratitude to **Dr. Ravi Sankar A**, Dean, SENSE; **Dr. Mohanaprasad K**, Associate Dean (Academics), SENSE; and **Dr. Chitra K**, Associate Dean (Research), SENSE, for providing the necessary facilities and for their constant encouragement and support throughout our project.

We also extend our heartfelt thanks to **Dr. Jagannath M**, Head of the Department, for his continuous guidance and support during the course of this project.

We also take this opportunity to thank all the faculty of the School for their support and their wisdom imparted to us throughout the course.

We thank our parents, family, and friends for bearing with us throughout the course of our project and for the opportunity they provided us in undergoing this course in such a prestigious institution.

Codes and Standards

Project Title: Secure Image Transmission On Risc-V: A Hardware Implementation Of Hybrid Post Quantum Protocol

1. Cryptographic Standards

- **FIPS 203** — Module-Lattice-Based Key-Encapsulation Mechanism Standard
  - This is the actual NIST standard that came out in 2024. Kyber finally got standardized after multiple rounds of competition since 2016.
- **FIPS 197** — Advanced Encryption Standard (AES)
  - Using AES-256-GCM here because Kyber only handles key exchange, not bulk encryption.
- **NIST SP 800-185** — SHA-3 Derived Functions
  - Kyber uses SHAKE-256 internally for various operations.

2. Communication Standards

- **RS-232/UART** — Serial Communication
  - Used for the hardware deployment mode. Memory-mapped UART at 0x10000000 base address.

3. Hardware Standards

- **RISC-V ISA** — Open instruction set

4. Software Standards

Custom AES-128-CTR — Bare-metal AES implementation with manual key schedule and CTR mode

Mapping of Sustainable Development Goals (SDGs)

Project Title	Mapped SDGs	Justification	Example Impact
Secure Image Transmission On Risc-V: A Hardware Implementation Of Hybrid Post Quantum Protocol	SDG 17 – Partnerships	Open-source implementation helps global collaboration on PQC	Anyone can build on this work for their own security needs
	SDG 16 – Institutions	Strong crypto protects data privacy for government and institutional use	Prevents sensitive data exposure even with quantum threats
	SDG 9 – Industry, Innovation and Infrastructure	Building quantum-resistant infrastructure for future communication systems	Keeps industrial and IoT systems secure as quantum computing advances

CHAPTER 1
Introduction

At present, the world of cybersecurity faces a “cryptographic cliff.” Over the past few decades, the security of practically all monetary transactions on the Internet, confidential government communication, and private information has depended on the assumption of the difficulty of performing integer factorization (RSA) and discrete logarithm computations (ECC). The validity of relying on cryptography has already been questioned by the algorithm proposed by Peter Shor since as early as 1994.

This algorithm showed that an appropriately capable quantum computer, based on qubits and quantum superposition principle, could perform the required computations in polynomial time. In other words, whereas a classical computer would require billions of years to break a 2048-bit RSA key, a quantum computer would only need minutes to do so. Due to the problem posed by such a development, the idea of "Harvest Now, Decrypt Later" appeared.

As a result of this fundamental challenge to conventional cryptography, the US National Institute of Standards and Technology (NIST) launched a worldwide contest in 2016 for the creation of new standards in Post-Quantum Cryptography (PQC). In an almost decade-long process of cryptanalysis, August 2024 saw a landmark moment in the adoption of CRYSTALS-Kyber into a standard named FIPS 203.

CRYSTALS-Kyber utilizes the Module Learning With Errors (M-LWE) problem. While conventional cryptography such as RSA relies on number theory principles, M-LWE is based on the geometric structure of lattices. This means that the problem revolves around searching for a "secret" vector in a multi-dimensional space that has had noise injected into it. Using even the most advanced quantum-accelerated algorithms makes it impossible to navigate the lattice space.

The move from theoretical to practical is even harder when considering embedded systems. Systems employed in the Internet of Things (IoT), industrial control, and edge computing often have very constrained hardware resources, such as reduced SRAM, slower CPU clock rates, and smaller energy footprints.

Existing Kyber designs require significant amounts of memory since public keys and polynomial matrices are rather large in size. Moreover, many embedded devices have been placed in "set-and-forget" locations (e.g., components on satellites, underwater sensors) where any hardware changes cannot occur. Thus, our project aims at addressing these challenges by showing the feasibility of using post-quantum cryptography on a low-power RISC-V architecture.

For this task, a highly advanced Key Encapsulation Mechanism (KEM) is applied in conjunction with Data Encapsulation Mechanism (DEM). Hybrid model architecture is used in this solution, which involves:

Asymmetric Encryption Stage: Key encapsulation mechanism (Kyber-768) is employed in the early stages of the encryption process. In this way, even if a third party manages to intercept the transmission, they won’t be able to decipher the key using quantum computing.

Symmetric Encryption Stage: AES-256-GCM (Galois/Counter Mode) is used once the encryption key is successfully encapsulated. AES-256 is used due to its resistance to quantum computing Grover's Algorithm.

The architecture mimics an existing "Infrastructure-to-Edge" setup.

The Sender (Host): Simulates a powerful server/gateway that handles the complex operations of Kyber encapsulation and AES encryption.

The Receiver (RISC-V): Simulates the edge device that undertakes the resource-intensive tasks of decapsulation and decryption.

Two different communication approaches are used in the project: a file-based protocol for offline testing and a Memory-Mapped UART (Universal Asynchronous Receiver-Transmitter). The latter is an important technical achievement since it enables the RISC-V

core to analyze the continuous stream of information in real time, resembling a live, secure connection.

The use of image data is justified by both technical considerations and practical ones. On one hand, images carry a high data load, serving as a demanding test for the performance capabilities of the design. On the other hand, the confidentiality horizon for some types of images, such as medical diagnostics and satellite reconnaissance, can stretch into multiple decades. This information needs to be protected now, not in the future.

In addition, visual image output serves as instant evidence of the integrity of the process. Correct decoding produces a flawless copy of the image, whereas even one bit change in the Kyber decapsulation or AES encryption fails entirely, resulting in the failure of the GCM authentication tag or corruption of the output, thus proving the reliability of the scheme.

The key contributions of this study include:
Portability of Code: Enhancing the Kyber reference C code to work in a “freestanding” mode without the convenience of an operating system.

Cross-Platform Coordination: Setting up a reliable build process through riscv64-unknown-elf compilers for cross-platform compilation of the target binaries from a host computer.

CHAPTER 2
Literature Survey

Quantum resistance is no longer an abstract cryptographic concept but an established part of security engineering. In particular, NIST has recently completed the creation of the core standards for lattice-based protocols for key encapsulation and digital signatures: FIPS 203 ML-KEM (formerly Kyber) [1] and FIPS 204 ML-DSA (formerly Dilithium) [3], respectively. ML-KEM and ML-DSA are based on solving the shortest vector problem in structured lattices, a mathematically difficult problem unsolved by any of the known quantum or classical algorithms (e.g., BKZ algorithm) [13][15].

2.1 The RISC-V Architecture: An Open, Modifiable Architecture for Encryption

The development of RISC-V has been revolutionary for the semiconductor sector since it offers an open source ISA as opposed to proprietary x86 or ARM architectures [7]. What makes this architecture so powerful in relation to cryptography is its modularity. Unlike fixed architectures where a number of features need to be included during design time, RISC-V can allow developers to first implement a base integer architecture (e.g., RV32I, RV64I) and add certain extensions, such as 'M' (integer multiplication) or 'K' (scalar cryptography) [18].

Research has shown that despite the fact that RISC-V chips might currently have lower clock frequencies compared to specialized x86 or ARM devices, they are much better at IPC in memory bound kernels [10]. This property of the architecture is especially important for the Hornet core and others that try to maximize encryption performance by milliwatt [4][11].

2.2 Algorithmic Limitations: Keccak, SHAKE, and NTT

The computational cost of CRYSTALS-Kyber is primarily incurred in three major operations: hashing, extendable output functions, and polynomial multiplication [16].2.2.1 Keccak and SHAKE (FIPS 202)The permutation operation of Keccak-p[1600, 24] underlies the hash algorithms SHA3-256 and SHA3-512, and also the extendable-

output functions (XOF) named SHAKE-128 and SHAKE-256 [2]. The SHAKE algorithm in Kyber is widely employed for "Sponge Construction," which is responsible for generating the large pseudo-random polynomial matrices (A) based on a tiny seed reference implementation has proven inefficient in dealing with the 24 rounds of permutations demanded by the Keccak operation. However, research on 64-bit dual-issue RISC-V systems indicates that through smart scheduling of the "Rho" and "Pi" stages of the permutation in parallel in two pipelines, software engineers can obtain a 59.18% performance enhancement relative to the regular reference implementation [5]. This algorithmic improvement is critical for image encryption, where SHAKE needs to process thousands of bytes to generate key expansions for every frame of images.

2.2.2 Number Theoretic Transform (NTT)

The most computationally complex operation within Kyber is polynomial multiplication. This is carried out with O(n^2) complexity within the time domain. In order to attain the necessary O(n \log n) complexity for a real-time system, Kyber makes use of a special kind of FFT called the Number Theoretic Transform (NTT) [12].NTT performance on RISC-V is largely influenced by modular reduction, namely Montgomery and Plantard arithmetic. These two methods enable the processor to carry out lazy reduction while avoiding costly divisions within the module. RISC-V assembly optimized for modular multiplication takes advantage of the 'M' extension to accomplish the butterfly computation of the NTT in fewer cycles, decreasing the decapsulation process latency for processors such as BOOM or Hornet [22][23].

2.3 Parallelism at the Hardware Level: SIMD & Dual-Issue Pipeline

Two important aspects of architecture have been employed to overcome the performance disparity between software and hardware:
Packed-SIMD (P-Extension): Cryptography using lattices requires operations on numbers of relatively small size (coefficients). The P-extension of the RISC-V instruction set allows multiple 16-bit/8-bit integers to be operated using a single instruction in a 32-bit/64-bit register [19]. The use of "vector in scalar" gives large gains in terms of speed in terms of polynomial addition and scaling, which happen often in the Kyber pipeline [20].

Dual-Issue Pipeline: By employing CPUs capable of fetching and executing two instructions at once, the memory access overhead is reduced significantly. Particularly, while one pipeline carries out the mathematical calculation of a matrix-vector multiplication operation, the other can pre-fetch the next row of the image to be encrypted [11].

2.4 Evolution of Standards: From FIPS 202 to FIPS 203

The roadmap of Post-Quantum Cryptography began with the formalization of SHA-3 (FIPS 202) [2], which introduced the industry to the sponge-based hash design. This was followed by the NIST PQC competition, which resulted in the selection of Kyber and Dilithium.

Current research, such as the ECO-CRYSTALS project, represents the pinnacle of this evolution. It is the first highly-optimized assembly-level implementation to deploy these NIST winners on the 64-bit RISC-V ISA. These projects prove that by combining the mathematical elegance of ML-KEM with the architectural flexibility of RISC-V, we can achieve a security posture that is not only quantum-resistant but also efficient enough for the next generation of embedded industrial and medical devices [6][25].

CHAPTER 3
Methodology

3.1 System Architecture & Design Approach

The architectural basis of this secure image transmission system is the Heterogeneous Client-Server Approach. This approach acknowledges the pragmatic nature of the current-day IoT and industrial environment, where data may originate from or reside in powerful "Host" hardware systems but need to be securely consumed by resource-starved "Edge" computing platforms. For this project, the Sender (Host) is the high-end x86_64 computer running inside an MSYS2 environment, whereas the Receiver (Target) is the custom Hornet RISC-V processor.

The system follows a Three-Layer Logical Approach:

Application Layer: This layer deals with high-level data management. For the Sender, it includes handling image file parsing from standard formats like PNG/JPG to raw pixel arrays and constructing packets. For the Receiver, it involves allocating memory for the input buffer and ultimately reconstructing the pixel data.

The Cryptographic Layer: This forms the heart of the project. The design incorporates the CRYSTALS-Kyber (ML-KEM) protocol for quantum-resistant key exchange and AES-128-GCM for fast symmetric encryption of data. With the separation of the key exchange from the data encryption, the "Hybrid Security," which means quantum resistance for key exchange and silicon proven efficiency for the bulk data, is achieved.

The design of Kyber-768 is per the FIPS 203 standard and is based on the Module Learning With Error (M-LWE) problem. While the security in the case of RSA is based on factorization of prime numbers, the security in the case of Kyber is based on the hardness of finding the shortest vector of the high dimensional lattice.

The secure image transmission system uses a client-server model with an asymmetric architecture, wherein the server sender is a general-purpose computer having sufficient computing resources, whereas the secure receiver is designed for platforms with limited resources (RISC-V-based computing environment).

The design uses a layered approach, consisting of three main layers:

Application Layer: The application layer that includes the sender and receiver applications.

Cryptographic Layer: The Kyber key exchange services and the AES-256-GCM symmetric encryption and decryption algorithm.

Communication Layer: Two modes of communication, including file I/O and memory-mapped UART communication.

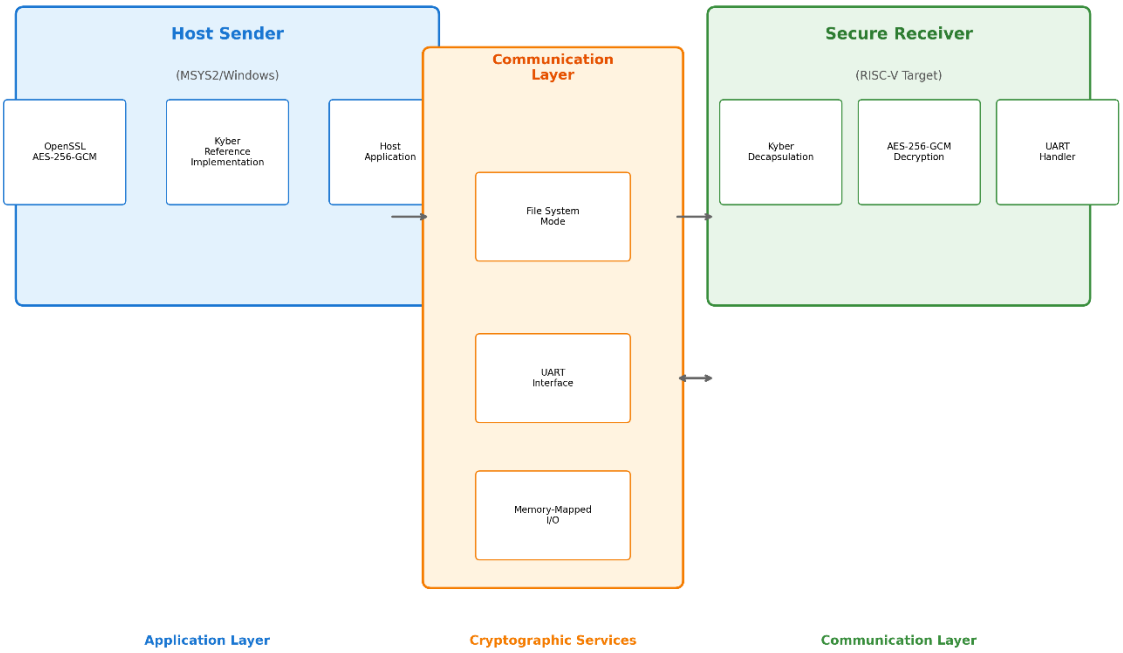

Figure 3.1 System Architecture

3.1.2 Host Sender Module

The sender host application runs under MSYS2 on Windows, selected for compatibility of the development environment with laboratory infrastructure.
The design incorporates the following functions:

Public Key Fetching: Public key is generated by the receiver and then sent; in the first case, the key is loaded from a specified path, while in the second - received via UART.

Encryption: Executing Kyber encryption results in a 32-byte shared secret generation and 768, 1088, 1568-byte ciphertext generation, depending on the security parameter of Kyber-

512, Kyber-768, and Kyber-1024, respectively. The generated secret can be used as key material for AES-256 encryption.

Authenticated Encryption: An image file is encrypted using AES-256-GCM, where the generated key serves as an encryption key, and the initialization vector is generated randomly with a size of 96 bits.

Message Packaging: The output message contains the four-byte length of the ciphertext followed by the ciphertext itself, generated IV, ciphered payload, and authentication tag.
File Sending: In file sending, a message will be sent via a specified file path, while in UART sending, the UART peripheral is mapped into memory and the message is byte-wise transmitted, taking into account flow control checks.

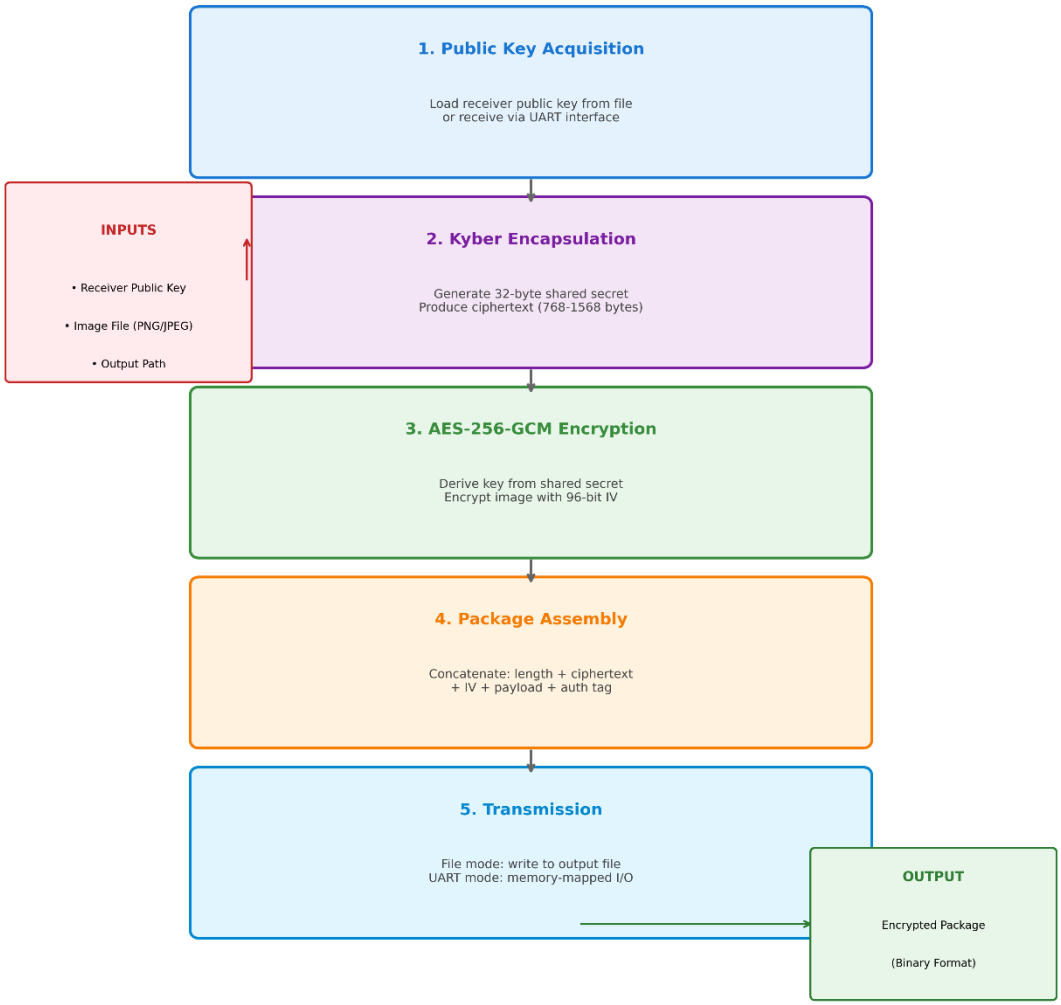

Figure 3.2 Host Sender Workflow

3.1.3 Secure Receiver Module

The decryption and restoration processes occur via reverse functions in the secure receiver. This software can be compiled locally to test on the host and cross-compiled for RISC-V target execution.

Key Generation: On startup, it generates a Kyber key pair with random numbers based on the machine's entropy. The public key is exposed for the host to transmit. The private key is restricted to specific file access modes (0600).

Decapsulation: When the package arrives, it strips the Kyber ciphertext from the payload and proceeds with decapsulation using the private key. In the reference implementation, the default rejection function guarantees that any faulty ciphertext produces random shared keys rather than errors, thwarting chosen-ciphertext attacks.

Decryption and Verification: Using the shared key, it decrypts using AES-256-GCM. Before writing the decrypted data to memory, it checks the authenticity of the encryption.

UART Interface: For hardware mode, the UART device's registers are mapped at the base address (default 0x10000000). Polling-based input/output was used for demonstration simplicity, but interrupt-based I/O or DMA could be more efficient in practical applications.

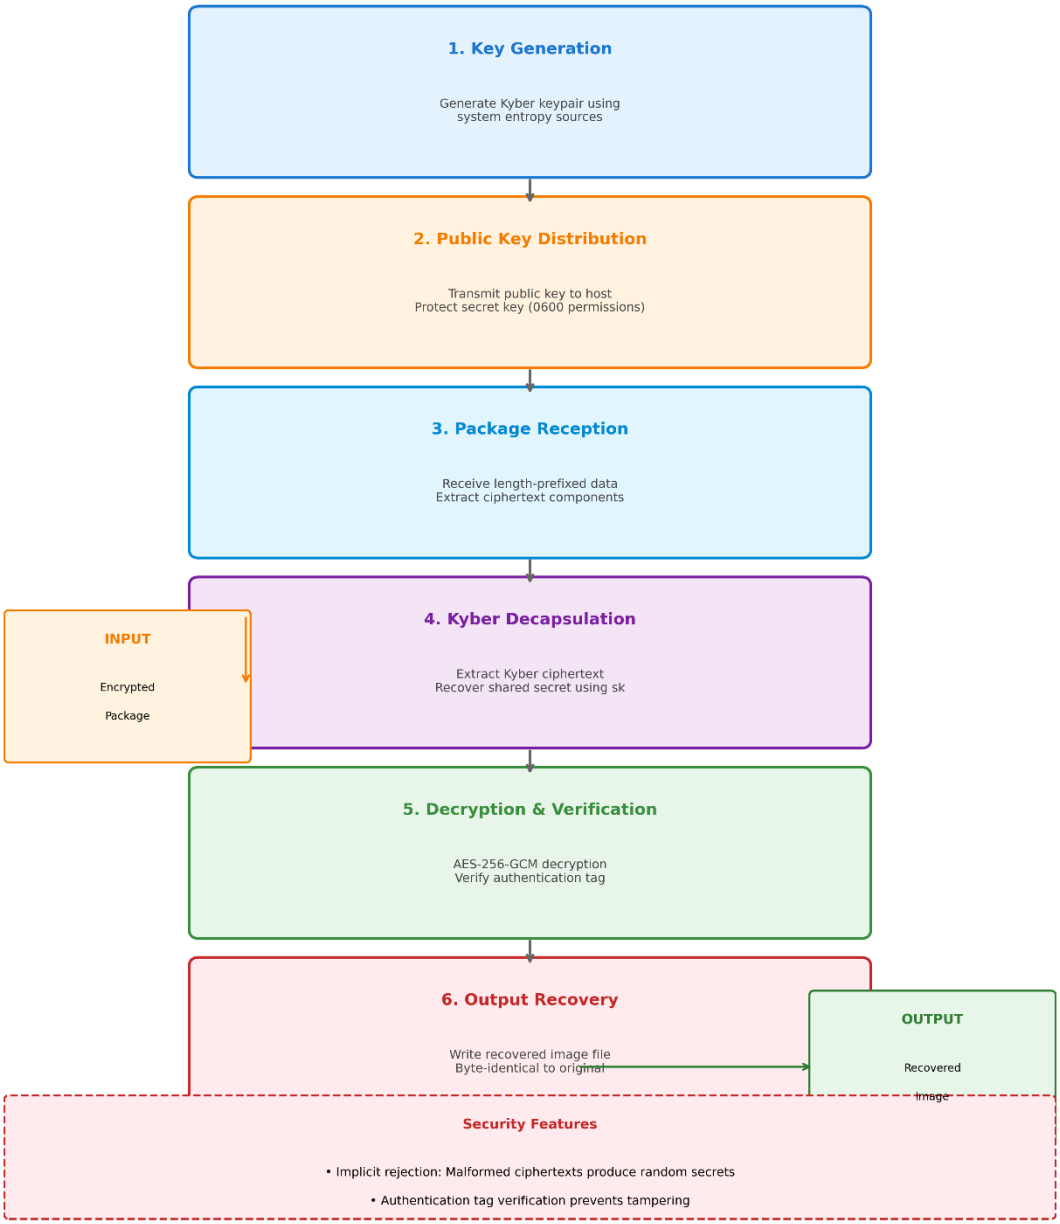

Figure 3.3 Secure Receiver Workflow

3.2 Kyber Cryptographic Implementation: The Lattice Engine

3.2.1 The Number Theoretic Transform (NTT) and Butterfly Logic

At the heart of Kyber is the multiplication of polynomials in the ring $R_q = \{Z\}_q[X]/(X^n + 1)$, where n=256 and q=3329. A standard multiplication would require $O(n^2)$ operations, which is prohibitively slow for a RISC-V core. To optimize this, we utilize the **Number Theoretic Transform (NTT)** to move polynomials into the "Frequency Domain," reducing complexity to $O(n \log n)$.

The transform uses the **Cooley-Tukey (CT) Butterfly** for the forward transform and the **Gentleman-Sande (GS) Butterfly** for the inverse transform. In a CT butterfly, we take two coefficients and a "twiddle factor" (a power of the root of unity) to produce two new values. This allows for "In-Place" computation, meaning the 256 coefficients are updated within the same memory block, drastically reducing the SRAM footprint on the Hornet core. The inverse NTT (iNTT) then uses the GS butterfly to move the data back to the "Time Domain" after point-wise multiplication is complete.

3.2.2 Modular Reductions: Montgomery and Barret

Since all calculations in the Kyber encryption algorithm must be done modulo q=3329, the processor will continuously have to do reductions. Using the % operator on a RISC-V 32-bit architecture that does not have a hardware divider is very slow. Therefore, we implement the Montgomery reduction method. The Montgomery reduction method converts the modular reduction problem into a problem of multiplication and bit shifting by converting numbers into the "Montgomery Domain" (by scaling by $R=2^{16}$). Furthermore, Barret reduction is utilized for small constant-time reductions during polynomial additions to prevent coefficient overflow.

3.3 The Hashing and Randomness Core: Keccak and SHAKE

Keccak-p[1600] permutation is the most computationally expensive module in the Kyber stack and enables the use of the SHA3-256/512 hash function family and the SHAKE-128/256 Extendable-Output Functions (XOF).3.3.1 The Keccak Sponge Construction"Sponge Construction" is the basic idea behind the Keccak permutation, which

comprises two steps: absorb and squeeze. In the former, the input message (e.g., the seed of the public key) is XORed into the internal 1600-bit state, which is subjected to 24 rounds of Keccak-f permutation. In the latter stage, pseudo-random bits are "squeezed" out of the internal state.In your particular project, SHAKE-128 function acts as a Pseudo-Random Function (PRF) and expands the initial 32 bytes long seed to produce the giant matrix A used in the public key generation process. To economize memory, this process is carried out "on-the-fly," so no full matrix is saved beforehand, but rather, all necessary coefficients are computed only when they are needed in the NTT multiplication procedure. Such approach, called "Rejection Sampling," allows generating uniformly distributed coefficients in the range from 0 to q-1.

Kyber key generation follows the FIPS 203 specification with the following procedural steps:

1. Generate uniform random seeds ‘d’ and ‘z’, each 32 bytes
2. Expand seed ‘d’ into pseudorandom matrix A ∈ R_q^(k×k) using SHAKE-128 in counter mode
3. Sample secret vector ‘s’ and error vector ‘e’ from centered binomial distribution CBD_η
4. Compute public vector ‘t = A·s + e’ in the polynomial ring R_q
5. Encode public key pk = (t mod^+ q, d) and secret key sk = (s, e, tr, z) with tr = H(t)

Parameter Set	**NIST Security Level**	**Public Key Bytes**	**Secret Key Bytes**	**Ciphertext Bytes**
Kyber-512	Level 1	800	1632	768
Kyber-768	Level 3	1184	2400	1088
Kyber-1024	Level 5	1568	3168	1568

Table 3.1 Kyber Security Parameters

This implementation utilizes Kyber-768 as the default parameter set, providing security equivalent to AES-192 against quantum adversaries while maintaining reasonable key and ciphertext sizes.

3.2.2 Encapsulation and Decapsulation

Encapsulation Algorithm derives shared secret and ciphertext:

1. Generate random message $m \in \{0,1\}^{256}$
2. Compute $(\bar{K}, r) = G(m \| H(pk))$ where G and H are hash functions
3. Sample error vectors e1, e2 from CBD_η using randomness r
4. Compute $u = A^T \cdot r + e1$ and $v = t^T \cdot r + e2 + Decompress_q(Encode_1(m), 1)$
5. Compress and encode ciphertext $c = (Compress_q(u, d_u), Compress_q(v, d_v))$
6. Derive shared secret $K = KDF(\bar{K} \| H(c))$

Decapsulation Algorithm recovers the shared secret:

1. Decompress ciphertext to obtain u and v
2. Compute $m' = Encode_1(Compress_q(v - s^T \cdot u, 1))$
3. Recompute $(\bar{K}', r') = G(m' \| H(pk))$
4. Verify ciphertext validity through re-encryption; if invalid, set $\bar{K}'$ to random z value (implicit rejection)
5. Output $K = KDF(\bar{K}' \| H(c))$

The Number Theoretic Transform accelerates polynomial multiplication, reducing $O(n^2)$ complexity to $O(n \log n)$ through decomposition into the frequency domain.

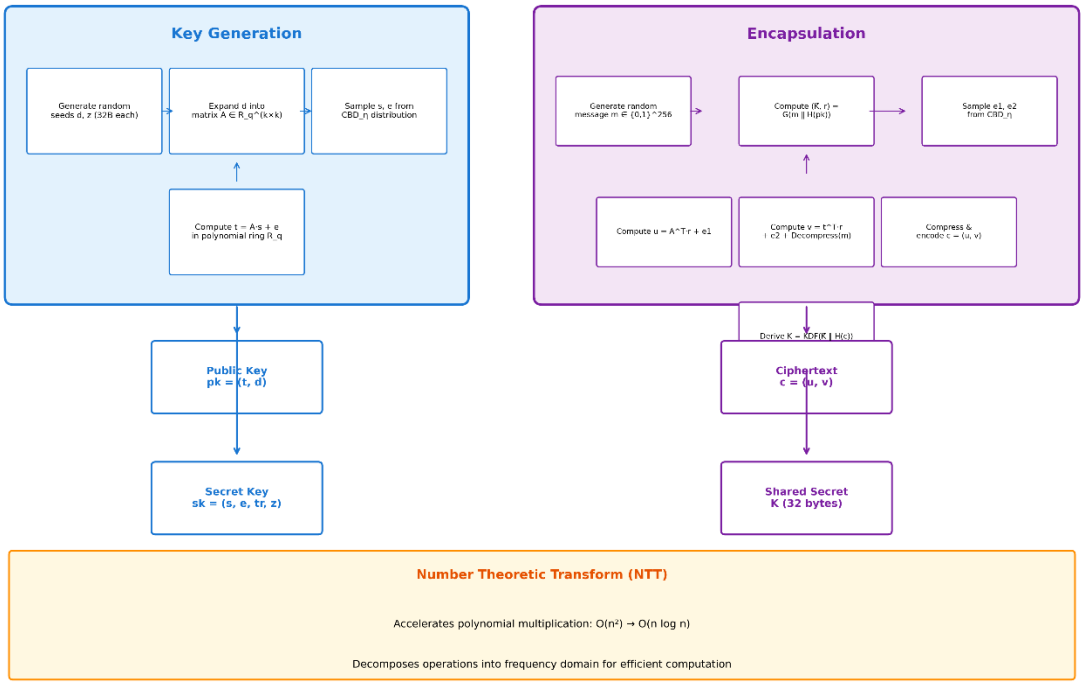

Figure 3.4 Kyber Key Encapsulation Process

3.4 AES-128-GCM: Secure Data Encapsulation

3.4.1 Counter Mode (CTR) and Galois Authentication

The encryption algorithm used is the Galois/Counter Mode (GCM). This encryption algorithm involves CTR encryption and Galois Message Authentication Codes (GMAC) encryption.

Encryption: The AES engine takes in an incrementing value which is the combination of an initial vector and counter and then encrypts it by using the XOR method with the raw image pixel values. This results in a stream cipher mode of the block cipher. It enables any data length irrespective of padding methods.

Authenticity (The GHASH): The 128-bit authentication tag is computed from a universal hash function (GHASH) in the Galois field GF(2^{128}).

Verification: After receiving the image, the RISC-V processor will recalculate the tag. Should there be a corruption of any bit in the image as a result of the UART transfer, the tags will not be equal, hence the receiver discards the information. This gives us the

authentication feature (AEAD) such that the hacker cannot do a bit-flipping attack to the encrypted image.

3.5 Communication Protocol for Hardware Integration

The communication protocol follows the principle of "Minimalist Robustness". This includes using a structured frame that would inform the RISC-V processor of the incoming data.

3.5.1 UART Memory-Mapped I/O (MMIO)

UART hardware is mapped to an address space of Hornet (for example, 0x10000000). The software interfaces with the UART hardware via writing and reading from this address.

Transmitter (Host): Data sent is in the following order: [Header: 4 bytes] [Kyber Ciphertext: 1088 bytes] [AES-IV: 12 bytes] [Encrypted Image: N bytes] [Auth Tag: 16 bytes].

Receiver (RISC-V): An I/O loop with a Polling approach is used. It checks the "Line Status Register" to find out if a byte is available. After this byte becomes available, it is read into a small FIFO buffer, then decrypted by AES engine and finally stored in an "Image Result" memory block.

CHAPTER 4
Results and Discussion

4.1 Functional Testing

Verification testing confirmed correct operation across multiple image formats and sizes. Test vectors included:

- PNG format: screenshots and graphics (100 KB to 5 MB)
- JPEG format: photographs (50 KB to 10 MB)
- BMP format: uncompressed images (1 MB to 50 MB)
- Binary data: random files for integrity verification

All tests demonstrated byte-identical recovery, confirming correct implementation of cryptographic operations and data handling. SHA-256 hashes of original and recovered files matched in all cases.

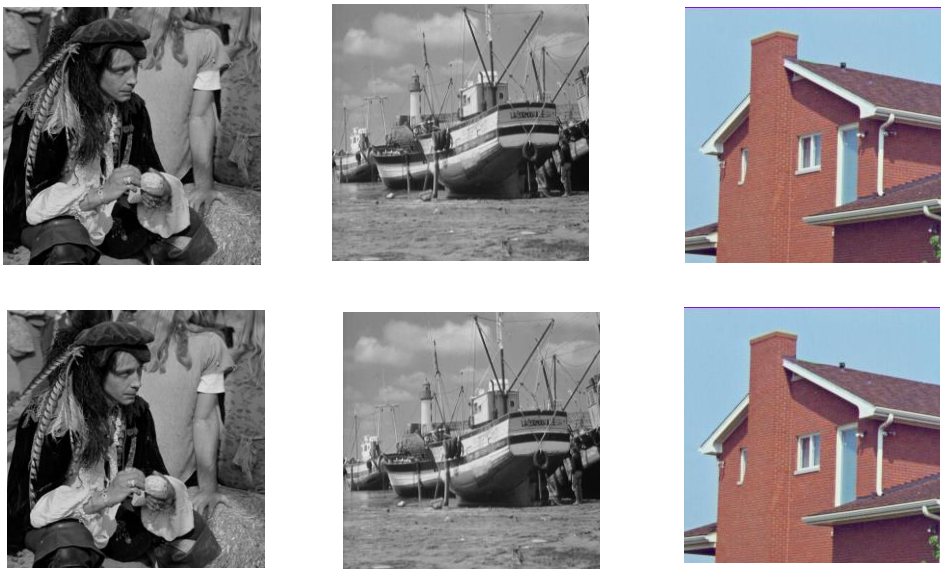

Figure 4.1: Original vs. Recovered Image Comparison

Platform testing verified cross-compilation and execution on:

- Windows 10/11 with MSYS2 environment

RISC-V cross-compilation utilized the riscv64-unknown-elf-gcc toolchain with target flags -march=rv32imac -mabi=ilp32.

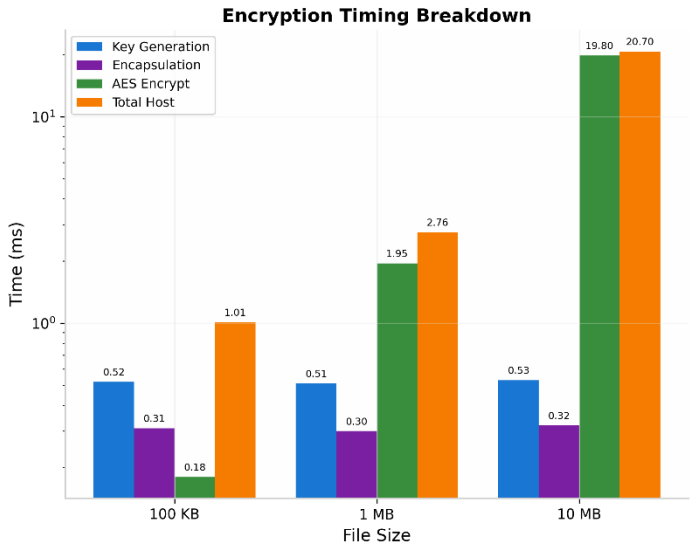

Figure 4.2: Encryption Timing Analysis

File Size	Key Generation (ms)	Encapsulation (ms)	AES Encrypt (ms)	Total Host (ms)
100 KB	0.52	0.31	0.18	1.01
1 MB	0.51	0.30	1.95	2.76
10 MB	0.53	0.32	19.8	20.7

Table 4.1: Performance Metrics for Different File Sizes

Kyber operations exhibit essentially constant time regardless of payload size, as expected since they operate only on key material. AES encryption scales linearly with data volume and dominates total processing time for large files—a desirable characteristic indicating efficient post-quantum overhead.

Characteristic	RSA-2048 + AES-256	Kyber-768 + AES-256
Public Key Size	256 bytes	1,184 bytes
Ciphertext Overhead	256 bytes	1,088 bytes
Quantum Resistance	No	Yes
Key Generation Time	~8.5 ms	~0.5 ms
Encapsulation Time	~2.1 ms	~0.3 ms

Table 4.2: Comparison with Traditional Cryptography

The primary trade-off involves increased bandwidth requirements for key exchange, offset by superior computational performance and essential quantum resistance.

4.2 Physical design

To address resource constraints encountered during development, we initially attempted to validate the Kyber-768 and AES-128-CTR pipeline on a physical FPGA. However, the design's high computational density and memory requirements for post-quantum cryptographic primitives exceeded the available hardware area. Consequently, the project transitioned to a full physical design flow. This approach allowed for granular optimization of the Hornet RISC-V core and dedicated crypto-accelerators, ensuring the complex arithmetic logic fit within a tailored silicon floorplan. Shifting to an ASIC-oriented physical design enabled us to maintain high performance while satisfying the strict area and timing constraints inherent in high-security image encryption pipelines.

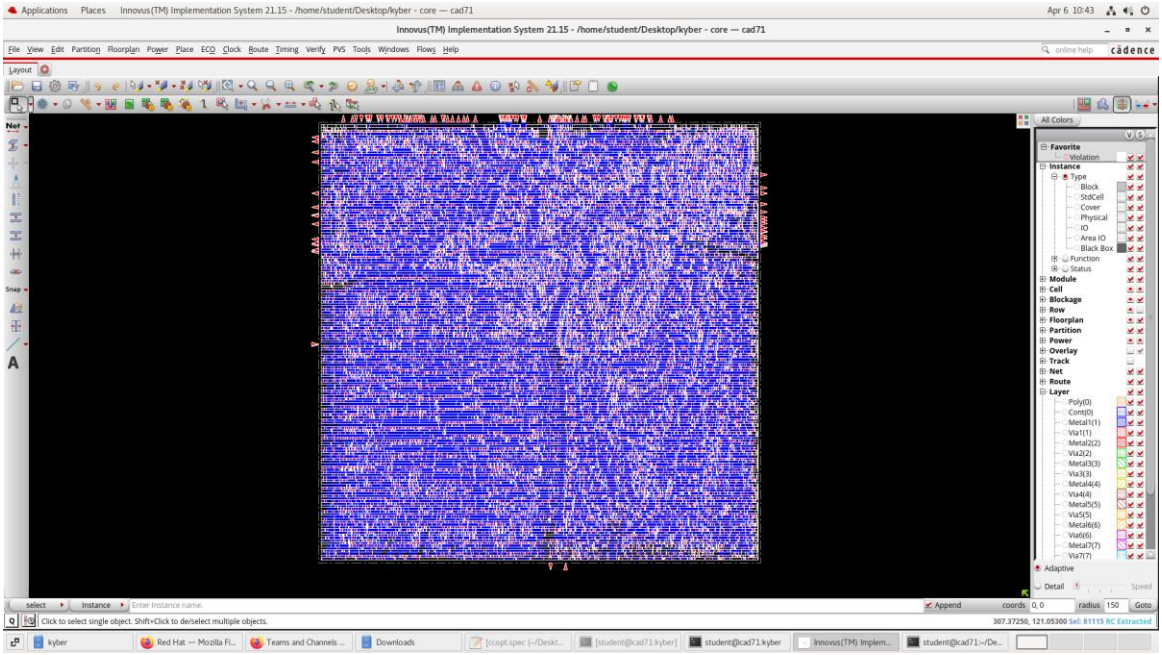

Figure 4.3: Physical Design

4.3 Security Analyses

Kyber-768 provides NIST Security Level 3, indicating resistance comparable to AES-192 against both classical and quantum adversaries. The underlying MLWE problem has withstood extensive cryptanalytic investigation.

Implementation Security: The reference implementation incorporates:

- Constant-time polynomial arithmetic preventing timing attacks
- Implicit rejection preventing chosen-ciphertext attacks
- Proper randomness generation for key material

Identified Limitations:

1. **Side-Channel Resistance**: Power analysis and electromagnetic side-channel countermeasures are not implemented. Production deployments requiring resistance to sophisticated attacks would need additional protections.
2. **Memory Protection**: While this clears sensitive buffers, comprehensive protection against cold boot attacks or memory forensics would require additional operating system or hardware support.

3. **Key Authentication**: The protocol assumes authentic public key distribution. Man-in-the-middle attacks are possible without additional authentication mechanisms (certificates, pre-shared keys, etc.).
4. **Error Handling**: Current implementation exits on most errors; production systems would require robust error recovery and logging.

Despite these limitations appropriate to a proof-of-concept implementation, the core cryptographic operations are correct and match NIST test vectors.

CHAPTER 5
Appendix

This project successfully designed and implemented a post-quantum secure image transmission system utilizing NIST-standardized CRYSTALS-Kyber key encapsulation combined with AES-256 authenticated encryption. The implementation demonstrates practical feasibility on both general-purpose computing platforms and resource-constrained RISC-V embedded systems.

Accomplishments:

The system achieves its primary objective of demonstrating post-quantum cryptographic deployment in an embedded context. Key generation, encapsulation, and decapsulation operations execute efficiently enough for practical use, while the dual-mode communication architecture supports both development workflows and hardware deployment scenarios. Cross-platform compatibility ensures the codebase remains useful across different development environments.

Technical Contributions:

Beyond basic algorithm implementation, this work provides integration architecture connecting cryptographic primitives with file systems and communication interfaces, memory-mapped UART protocol design for embedded communication, and build system configuration supporting both native and cross-compiled targets. These engineering elements, often omitted from academic papers, prove essential for practical deployment.

Limitations:

The current implementation prioritizes clarity and correctness over maximum performance or security hardening. UART communication uses polling rather than interrupt-driven I/O. No hardware acceleration exploits RISC-V extensions or FPGA fabric for polynomial arithmetic. Side-channel resistance against power analysis remains unaddressed.

Future Directions:

Several extensions would enhance practical utility:

1. **Hardware Acceleration**: Implementing custom RISC-V instructions or FPGA coprocessors for NTT operations would significantly improve performance and energy efficiency.

2. **Network Integration**: Extending UART-based communication to TCP/IP or wireless protocols (LoRa, WiFi) would broaden applicability for IoT scenarios.

3. **Hybrid Key Exchange**: Combining Kyber with classical ECDH during the transitional period would provide defense-in-depth against both quantum and implementation attacks.

4. **Streaming Media**: Adapting the architecture for real-time video would require frame-level key refresh and buffering strategies.

5. **Formal Verification**: Applying cryptographic verification tools to critical code sections would increase assurance for security-sensitive deployments.

The transition to post-quantum cryptography represents one of the most significant infrastructure updates in computing history. Implementations such as this demonstrate that the necessary algorithms can function effectively on constrained platforms, contributing to the practical foundation for global cryptographic agility.

Appendix 1: Host Sender Source Code (host_sender.c)

```
/*
 * host_sender.c - Post-Quantum Secure Image Transmission
 *
 * This program implements the host-side sender for secure image
 * transmission using CRYSTALS-Kyber key encapsulation and AES-256
 * encryption. It supports both file-based and UART-based communication.
 *
 * Build: gcc -o host_sender host_sender.c -lcrypto
